Abstract

The hepatic injury induced by carbon tetrachloride (CCl₄) as well as gamma-irradiation has taken most attention. Prevention is one of the essential ways of controlling this toxicity and the use of natural plant compounds as grape seed extract can be considered as one of the most significant elements in this prevention. The present study is also designed to evaluate the hepatoprotective effects of grape seed extract (100mg/kg B.wt daily) against the toxic effect of CCl₄ (0.3 ml/kg B.wt twice weekly for 8 weeks) and/ or fractionated doses of 2 Gy γ -radiation day after day up to 10 Gy in male rats.

Results obtained could be summarized as follows: Combined treatments of CCl₄ and γ -radiation induced a significant increase in malondialdehyde (MDA) level, and decreased level of reduced glutathione (GSH). It also increased serum enzymes aspartate transferase (AST), alanine transferase (ALT), alkaline phosphatase (ALP) and gamma - glutamyl transpeptidase (γ -GT) activities and decreased Hb%, RBCs, WBCs and platelets count. Proanthocyanidin administration improved the significant increase in MDA level and ameliorated serum enzymes as well as improved the decreased level of GSH content of irradiated rats or those treated with CCl₄. It also could normalize the blood constituents Hb%, RBCs, WBCs and platelets count. The data of the present study declared that proanthocyanidin is bioavailable, potent free radical scavenger and exhibits antioxidant properties against CCl₄ and gamma-irradiation induced hepatic injury.

Introduction

Virtually occupational exposures to toxic concentrations of carbon-tetrachloride vapours are possible during industrial use of the chemicals (NCI, 1985). It has been reported that oral exposure produced marked central nervous system depression and remarkable liver injury (Piyachaturawt *et al.*, 1995).

Injury produced by CCl₄ seems to be mediated by reactive metabolite-trichloromethyl free radical (CCl₃) formed by hemolytic cleavage of trichloromethyl peroxy free radical (Cl₃COO) formed by the reaction of CCl₃ with O₂ (Slater, 1982), which attach enoic fatty acids in the membranes of endoplasmic reticulum, leading to secondary free radicals, which

are subjected to attack by oxygen, and subsequent process, termed lipid peroxidation, which produces damage to membranes and enzymes (Poli *et al.*, 1989).

The beneficial properties of flavonoids, including proanthocyanidins, have been extensively researched (Murray and Pizzorno, 1999). In addition to their antioxidant and free radical scavenging activity (Faria *et al.*, 2006), proanthocyanidins found in grape seed extract have been reported to have antibacterial, anticarcinogenic, antiviral, anti-allergic, anti-inflammatory effects (Blazso *et al.*, 1994) vasodilatory actions (Bagchi *et al.*, 1998), antimutagenic agents, provide cardioprotection by maintaining vascular permeability

(Bagchi *et al.*, 2003) and the maintainance of DNA integrity (Bagchi *et al.*, 1998).

Material and Methods

Animals:

A total of 120 male Albino rats weighing 130-140 gm were used as experimental animals. The rats were housed 6 animals/cage with controlled air, temperature and relative humidity and maintained on standard cube pellets with free access to water. The diet consisted of not less than 20% protein, 5% fibers, 3% fats, 6.5% ash and supplied with vitamins and minerals mixture.

Gamma –irradiation procedure:

Irradiation process was performed using Gamma Cell-40 achieved by Egypt's National Center for Radiation Research and Technology (NCRRT), Cairo. The dose rate was 0.66 Gy/min. at the time of experimentation.

Chemicals:

Grape Seed extract (Proanthocyanidin) was purchased from Natur's Purest (West Los Angeles, CA 90025). it was dissolved in DMSO and diluted to the appropriate concentration by sterilized saline solution. Carbon-tetrachlorid was diluted to the appropriate concentration by olive oil.

Animal groups:

The experimental animals were divided into 8 groups (each group contains 15 rats) as follows:

Group1: Untreated control rats.

Group2: Animals were exposed to fractionated doses of γ -irradiation (2Gy ,day after day, up to 10 Gy).

Group3:Animals were injected intraperitoneally (i.p.) with CCl₄ alone (0.3ml/kg B.wt) twice weekly for 8 weeks (Yasuda *et al.* , 2000).

Group4: Animals were first treated with CCl₄ as described in group 3 (0.3 ml/kg B.wt.) and then exposed to fractionated doses of γ -irradiation (2Gy, day after day, up to 10 Gy).

Group5: Animals were given orally a natural antioxidant (Proanthocyanidine) daily for one week at a dose of 100 mg/kg B.wt (Bagchi *et al.*, 2001).

Group6: Animals were first given proanthocyanidin orally (daily for one week at a dose of 100 mg/kg B.wt), then exposed to fractionated doses of γ -irradiation (2Gy day after day up to 10 Gy).

Group7: Animals were given proanthocyanidin orally (daily for one week at a dose of 100 mg/kg B.wt), before the i.p. injection with CCl₄ and continuing for another 8 weeks parallel with the injection of CCl₄ (0.3 ml/ kg B.wt.)

Group8: Animals were given proanthocyanidin orally (daily for one week at a dose of 100 mg/kg B.wt), before the injection with CCl₄ and continuing for another 8 weeks parallel with the injection of CCl₄ (0.3mg/kg B.wt) followed by exposure to fractionated doses of γ -irradiation (2Gy, day after day, up to 10 Gy). All experimental groups were sacrificed after one day, 7 days, and 14 days post treatment or irradiation.

Biochemical studies:

Animals were sacrificed by slight ether anesthesia. A portion of blood samples were immediately collected and used for the determination of reduced glutathione (GSH) level as described by Beutler, (1963) as well as WBCs, RBCs, Hb %, and thrombocyte count were estimated according to Dacie and Lewis (1991). Another portion of blood was taken for the separation of serum for the determination of malonedialdehyde (MDA) according to the method of Yoshioka *et al.*, (1979). AST, ALT, ALP and γ -GT were measured as described by Reitman and Frankel (1957), John and Bauer (1982) and Szasz (1969) respectively. The data were statistically analyzed following the student's test (t) (Snedecor and Cochran 1980).

Results

Exposure of rats to whole body γ -irradiation or those received CCl₄ induced

significant increases ($P < 0.05, 0.01$) in the level of serum ALP activity all over the experimental periods as compared to control group. Additionally irradiated rats received CCl_4 exhibited highly significant increases in serum ALP activity reached 102.58, 55.94 and 18.68% at the investigated periods respectively (Fig.1).

On the other hand, pretreatment of irradiated rats or those received CCl_4 with proanthocyanidin induced a great amelioration in serum ALP activity in both groups. This was evident as the level of serum ALP activity was restored and recorded non-significant changes as compared to control group after 7 and 14 days of treatment.

Significant increase ($P < 0.05- 0.001$) in serum γ -GT activity was recorded due to whole body γ - irradiation and / or treatment of rats with CCl_4 as compared to control group (Fig.2). Pretreatment of irradiated rats with proanthocyanidin induced a limited improvement in serum γ -GT activity at 1,7 days post-irradiation, while a great amelioration was observed in serum γ -GT after 14 days post-irradiation, recording non-significant change as compared to control group. In addition, the antioxidant proanthocyanidin could restore the level of serum γ -GT activity in rats exposed to γ - irradiation and received CCl_4 . This was evident as the level of serum γ -GT activity recorded non-significant changes as compared to control group after 7 and 14 days of treatment as shown in Fig.(2).

The data obtained in Fig. (3 & 4) revealed highly significant increases ($P < 0.01 - 0.001$) in serum ALT and AST respectively in both groups of animals either exposed to fractionated doses of γ -radiation or received CCl_4 or those received both treatments all over the experimental periods. Administration of proanthocyanidin to irradiated rats or those received CCl_4 induced a great amelioration in serum ALT activity in both groups. In addition, pretreatment of irradiated rats with CCl_4 and proanthocyanidin improved the significant increase in serum ALT activity in respect to the irradiated and CCl_4 treated groups even though its level was still higher than the control group (Fig.3) . In addition, proanthocyanidin succeeded in restoring the

level of serum AST activity in rats exposed to γ - irradiation and received CCl_4 . This was manifested as the level of serum AST activity recorded non-significant changes as compared to control group after 14 days of treatment (Fig.4).

Significant decrease ($P < 0.05, 0.001$) in the levels of total leucocyte, erythrocytes count and Hb % was recorded in rats exposed to radiation or received CCl_4 or treated with both of them as illustrated in Fig. (5, 6 & 7) respectively.

On the other hand, pretreatment of irradiated rats with proanthocyanidin induced a great amelioration in total leucocytes count especially after 14 day of treatment (Fig. 5).

In addition, pretreatment with proanthocyanidin to rats exposed to γ - irradiation and received CCl_4 induced non-significant change in total erythrocytes count throughout the experimental intervals reflecting the protective effect of proanthocyanidin (Fig. 6).

Furthermore, administration of proanthocyanidin could restore the level of blood Hb % in rats exposed to γ -irradiation and received CCl_4 as manifested by a non-significant changes in Hb % compared to control values after 1, 7 and 14 days of treatment (Fig. 7).

Thrombocyte counts in the investigated groups approximately matched the changes occurred in leucocyte, erythrocytes count and Hb % all over the experimental periods (Fig. 8).

Figure (9) demonstrate that rats exposed to whole body γ - irradiation or received CCl_4 induced a significant increase ($P < 0.05 - 0.001$) in the level of MDA all over the experimental periods as compared to control group. On the other hand, pretreatment of irradiated rats or those received CCl_4 with proanthocyanidin induced a great amelioration in MDA in both groups. In addition, proanthocyanidin succeeded in restoring the level of MDA in rats exposed to γ - irradiation and received CCl_4 . This was evident as the level of MDA recorded non-significant changes as compared to control group after 14 day of treatment.

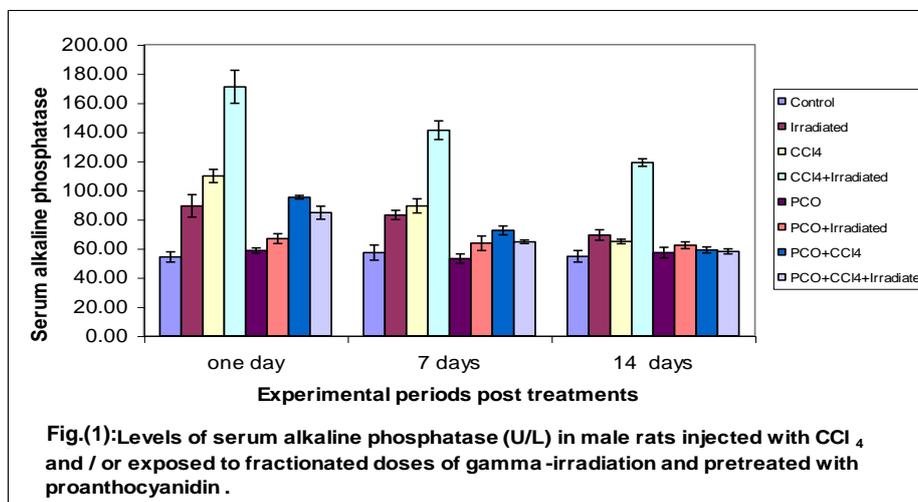

Exposure of rats to whole body γ -irradiation or treated with CCl_4 induced a significant decrease ($P < 0.01- 0.001$) in the level of blood GSH content all over the experimental periods as compared to control group (Fig. 10).

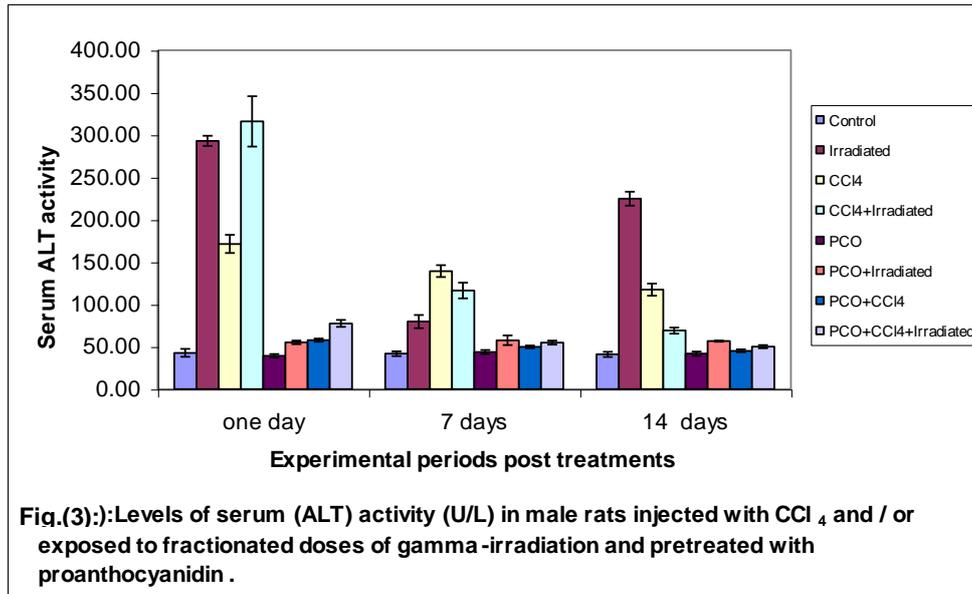

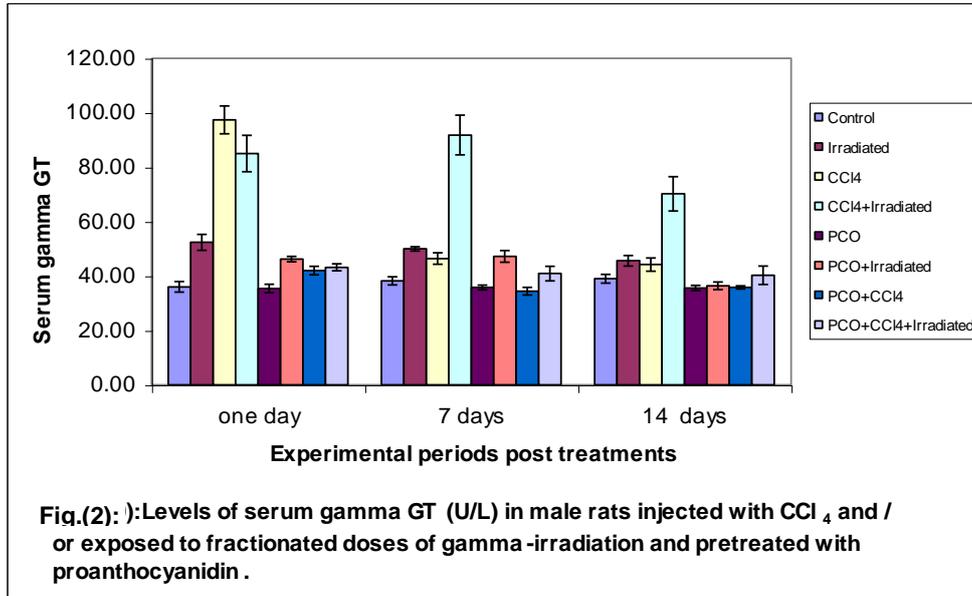

Irradiated rats received CCl_4 exhibited highly significant decreases in blood GSH all over the experimental periods reflecting the synergistic effects of both treatments on GSH level.

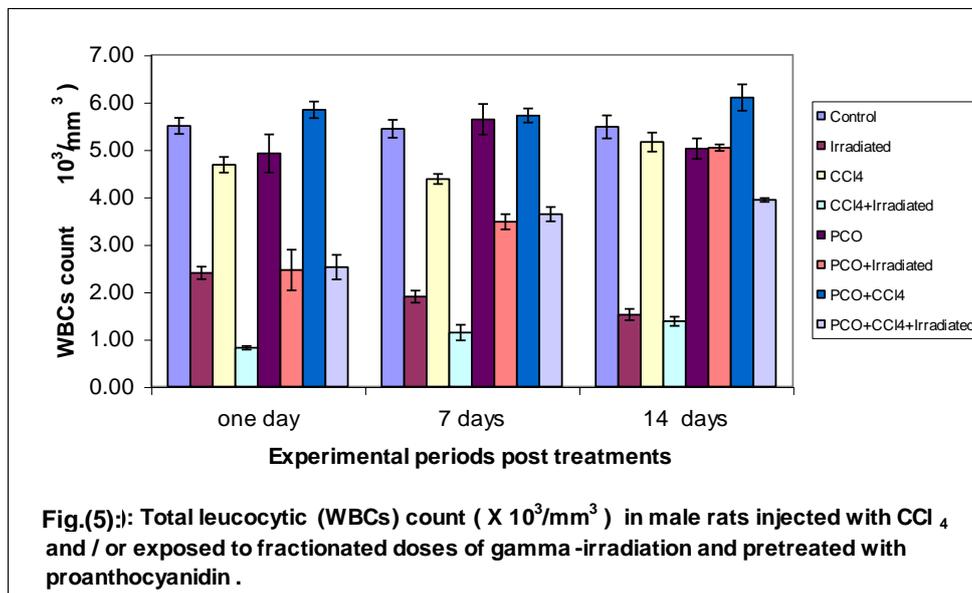

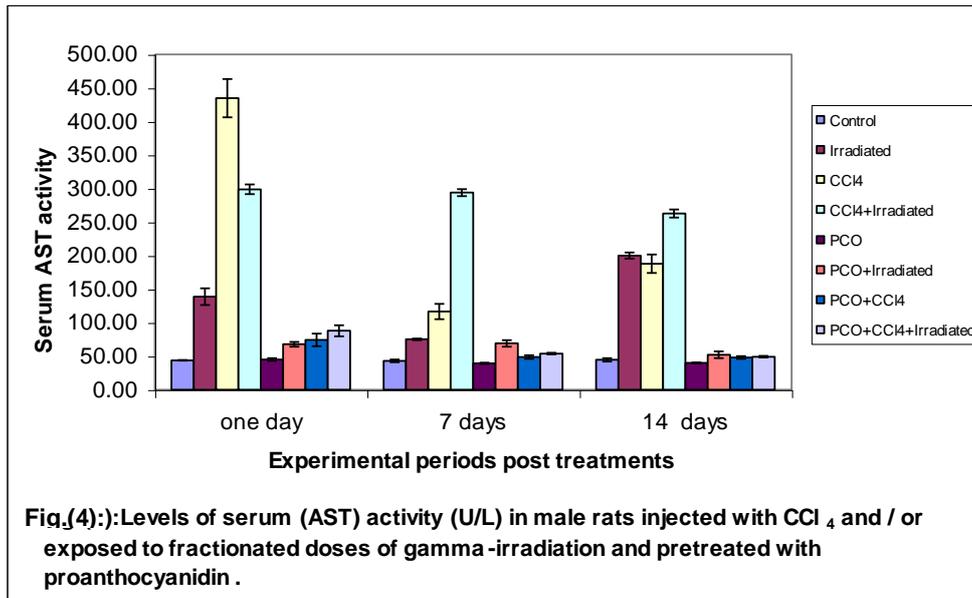

Non-significant change in blood GSH was observed in rats received the proanthocyanidin alone. On the other hand,

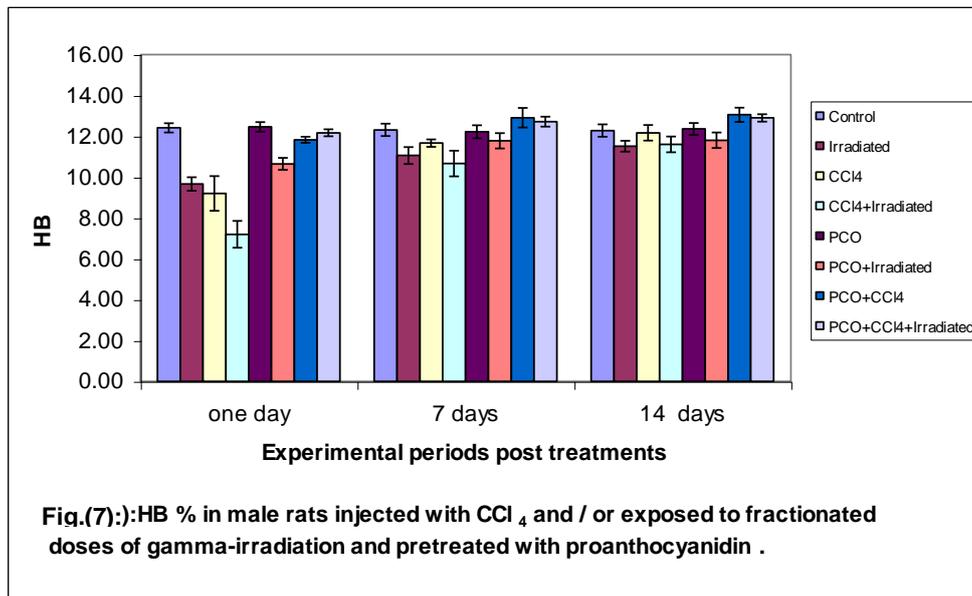

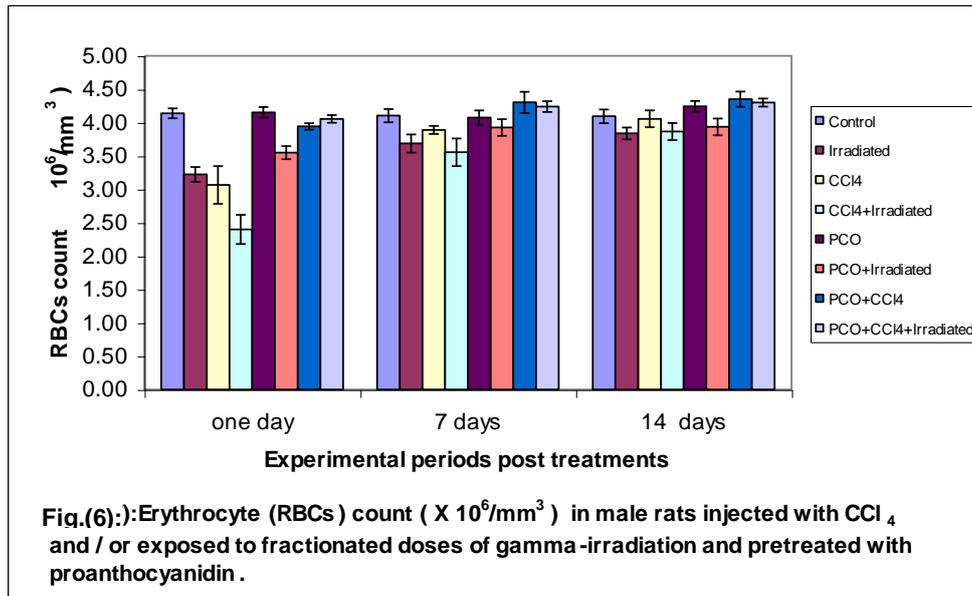

pretreatment of irradiated rats or those received CCl_4 with proanthocyanidin induced a great amelioration in blood GSH in both groups. In addition, the proanthocyanidin improved the level of blood GSH in rats exposed to γ - irradiation and received CCl_4 . This was evident as the level of GSH recorded non-significant changes as compared to control group after 7 and 14 days of treatment.

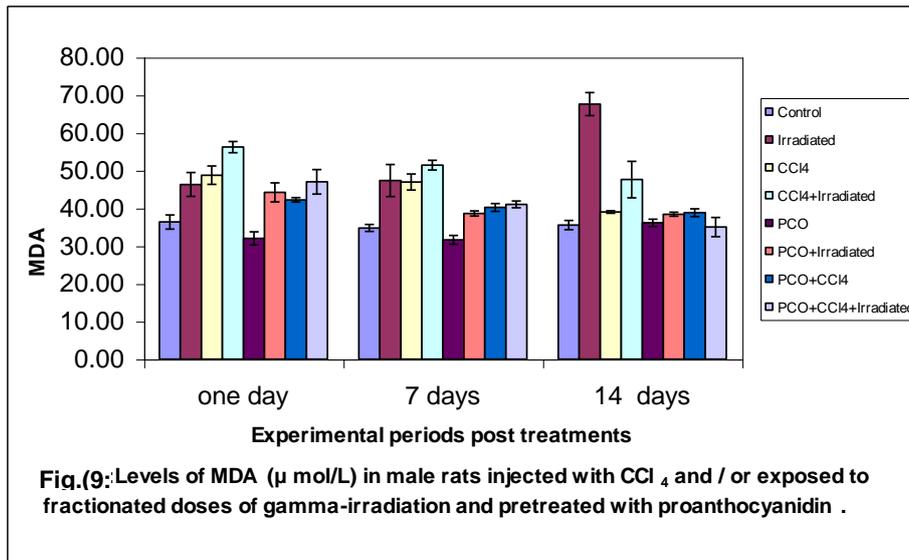

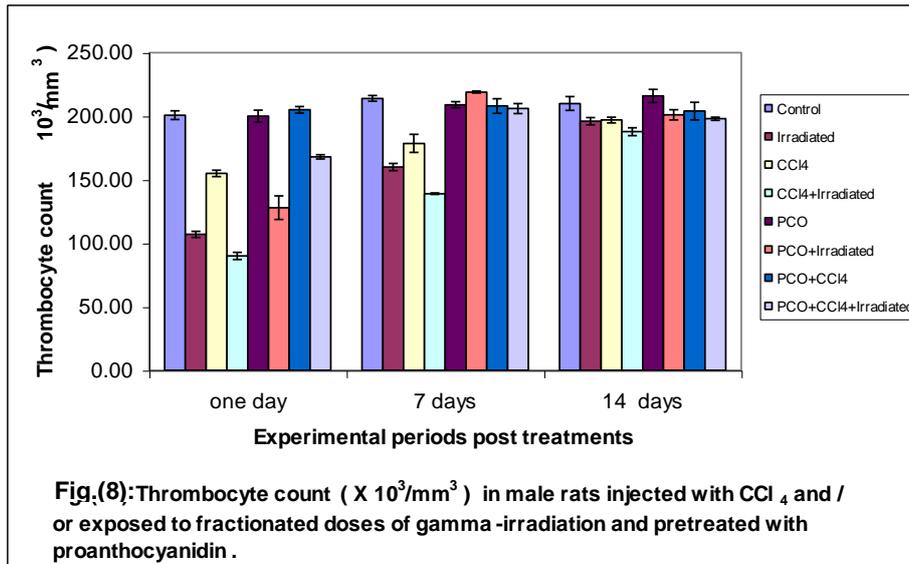

Non-significant changes in the investigated parameters were observed in rats received the proanthocyanidin alone.

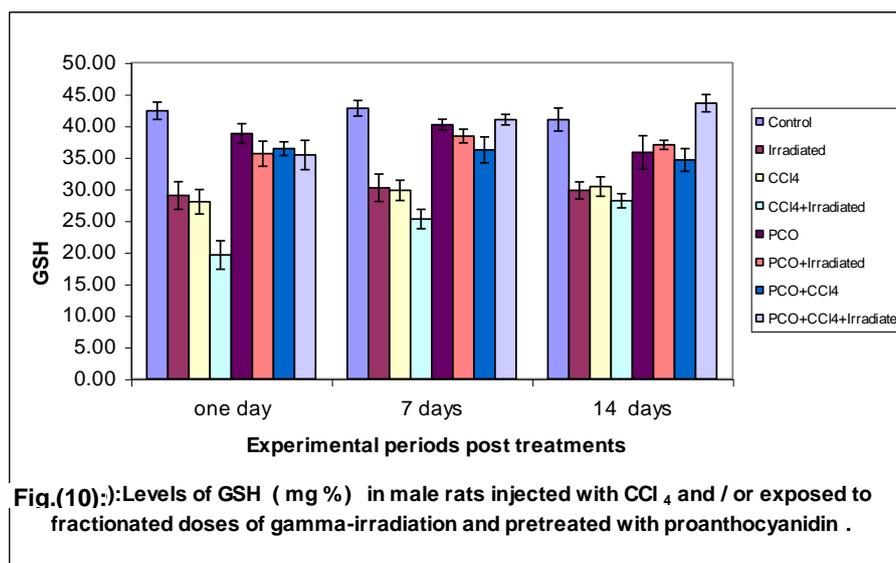

Discussion

The data of the present study revealed a disturbance in serum enzymes AST, ALT, γ -GT and ALP activities. These results run in agreement with the results of many authors (Abu-Ghadeer and El-Gawish, 1996; Abdel-Fattah and Saad El-Deen, 1997 and Kamat *et al.*, 2000). The changes in transaminases may attributed to the hepatocellular injury as a result of irradiation exposure, which in turn led to release of the enzymes from the hepatic cells into the blood stream (Weiss and Landauer 2003); Abou-Seif *et al.*, 2003).

Data of the present study have indicated that whole body γ -irradiation resulted in disorders in the haematological constituents as manifested by drop in leucocyte, erythrocyte, Hb % and thrombocyte counts. Similar observations were obtained by Hassan *et al.*, (1994) and Abu-Ghadeer and El-Gawish, (1996). The reduction in total leucocytic, erythrocyte, and thrombocyte count after radiation exposure observed in this study may be due to mitotic inhibition of the bone marrow precursors. Since, the basic designation of the bone marrow is the production of mature highly differentiated blood cells, accordingly, radiation exposure might depress the ability of bone marrow to produce its cells (Martin and Harbison,

1986). As the number of stem cells in the bone marrow decreases, a corresponding decrease would be exhibited in the number of the respective mature circulating cells. The radiosensitivity of the blood forming tissues was recognized early in the history of radiobiology. In human, blood platelets and neutrophils count decreased after local radiotherapy (Mohiuddin *et al.*, 1996). This could be attributed to direct destruction of the mature circulating cells, loss of cells from circulation by haemorrhage or leakage through capillary wall, and loss of production of cells. Since the blood cells have a definite life span, they must be constantly renewed by cell production in the haemopoietic tissues. If such cell population is inhibited, replacement of circulating cells will not occur. So, depressed haemato-poiesis is a major factor in decreasing the numbers of circulating cells.

Two mechanisms were suggested to explain the reduction in Hb concentration due to irradiation. Firstly, blockage the incorporation of iron into Hb due to disturbance in the biogenesis structure of the Hb molecule as evidenced by pronounced hyper-ferraemia post-irradiation. Second, oxidation of Hb iron causing loss of the biological structure and activity of Hb molecule (Nunia and Goyal, 2004).

The results of the present study showed that whole body γ -irradiation seriously stimulated lipid peroxidation production. This was evident from the highly significant increase in MDA as one of the main end products of lipid peroxidation. The recorded increase in MDA could be explained on the basis of that ionizing radiation induced lipid peroxidation through the production of active oxygen species, which attack the polyunsaturated fatty acids of the phospholipids of cell membrane (Gatsko *et al.*, 1990).

In the view of the data obtained in the present work, there was a significant decrease in blood glutathione. Such decrease was in accordance with the data reported by EL-Gawish *et al.* (1997 & 2000) and Abou-seif *et al.* (2003), Badr-El-Din (2003). The recorded decrease in the reduced GSH could be attributed to its conversion to the oxidized form with minimal chance to be recycled to the reduced form again due to inhibition of GSH reductase (Kergonou *et al.*, 1986). Jiangui and Sun (1993), found a correlation between the increase of lipoperoxide in irradiated mice and the decrease of the antioxidant defense system. This decrease in the scavenging system located extracellularly and intracellularly gives rise to excessive production of free radicals.

The data of the present study revealed that administration of CCl_4 induced similar changes in the investigated parameters to those exposed to γ -radiation. Injury produced by CCl_4 seems to be mediated by reactive metabolite-trichloromethyl free radical ($\cdot\text{CCl}_3$) formed by the hemolytic cleavage of trichloromethylperoxy free radical ($\text{Cl}_3\text{COO}\cdot$) formed by the reaction of $\cdot\text{CCl}_3$ with O_2 (Slater, 1982). This biotransformation is catalyzed by a cytochrome P450-dependent monooxygenase to yield trichloromethyl and chlorine free radicals. The trichloromethyl free radical is then thought to attach enoic fatty acids in the membranes of the endoplasmic reticulum, leading to secondary free radicals within the fatty acids, which is subjected to attack by oxygen, and the subsequent process, which is termed lipid peroxidation, produces damage to membranes and

enzymes (Poli, 1989). Thus the toxicity of CCl_4 depends on the cleavage of carbon-chloride bond to generate trichloromethyl free radical ($\cdot\text{CCl}_3$) (Lee *et al.*, 2004). Consequently, the CCl_4 -derived free radicals can initiate a process of autocatalytic lipid peroxidation by attacking the methyl bridges of unsaturated fatty side-chains of microsomal lipids (Yan *et al.*, 2003).

The decline in glutathione content together with increased lipid peroxidation following CCl_4 administration were reported by Kus *et al.*, (2004); Shukla *et al.*, (2004) and Valcheva *et al.*, (2004).

CCl_4 treatment generates free radicals that trigger a cascade of events resulting in liver dysfunction (Luo *et al.*, 2004 and Aziz *et al.*, 2005) as reflected by significant increase in serum AST, ALT, ALP and γ -GT activities (Gao *et al.*, 2004; Ha *et al.*, 2005),

The data of the present study proved that oral administration of proanthocyanidin ameliorated all the investigated parameters in animals exposed to fractionated doses of gamma-irradiation or treated with CCl_4 . Our results are in agreement with Bagchi *et al.*, (1998), Ray *et al.* (2000), Abou seif *et al.*, (2003) and Weiss and Landauer (2003).

Proanthocyanidins, a group of polyphenolic bioflavonoids, have been reported to exhibit a wide range of biological, pharmacological and chemoprotective properties against oxygen free radicals (Bagchi *et al.*, 1997, 2002 and Ray *et al.*, 2000).

It has been reported by Bagchi *et al.*, (1999), that proanthocyanidin provided significant protection against acute and chronic stress-induced gastrointestinal and hepatic oxidative injury as demonstrated by reduced lipid peroxidation, DNA damage and membrane microviscosity.

Grape seed extracts (GSE) contain a total of 92% to 95% the gallic esters of proanthocyanidins (PCO) (Veluri *et al.*, 2006). These compounds are the most active free radical scavenging PCOs (Bagchi *et al.*, 1998). GSE recycles and significantly extends the lifetime of vitamin C and potentiates vitamin E, and thereby creates a more powerful, synergistic

antioxidant defense in the body. This is important because vitamins C and E are key players in the body's protective antioxidant army, and by increasing the activity of vitamins C and E in the body, GSE helps the body to maintain its antioxidant defenses (Masquelier, 1996).

Grape seed extract showed potent antioxidant activity by trapping free radicals and antioxidative fats (hydroxyl and lipid free radicals, free iron molecules, and lipid peroxides), delaying fat oxidation, inhibiting the major substance responsible for generating oxygen-derived free radicals (xanthine oxidase) and reducing the concentration of H₂O₂ produced by oxidative stress (Sugisawa *et al.*, 2004).

Wang *et al.*, (1999) reported that proanthocyanidin could reduce the aggregation of platelets, increase the red blood cell pliability, decrease blood viscosity and increase fibrinolytic activity. In addition, proanthocyanidin improves the oxygen carrying capacity of blood, increases the strength and elasticity of blood vessel wall by binding with collagen. Flavonoids in general and proanthocyanidins in particular are free of side-effects, since they are water soluble, any excess proanthocyanidins are excreted via sweat or urine. So grape seed extract can be used safely and effectively in conjunction with other antioxidants plus the minerals (Yamakoshi *et al.*, 2002). Proanthocyanidin from grape seeds have been reported to show various beneficial properties including hepatoprotective effects as well as modulatory role on age-related oxidative DNA damage (Balu *et al.*, 2006).

الذرية.

قسم علم الحيوان – كلية العلوم – جامعة الازهر- فرع البنات*

استهدفت هذه الدراسة تقييم دور مستخلص بذور العنب الذى يحتوى على مادة البروانثوسيانيدىن كاحد المواد الطبيعية المضادة للأكسدة للحد من بعض الاختلالات البيوكيميائية التى تحدث نتيجة التعرض للإشعاع الجامى (2جراى خمس مرات يوم بعد يوم) أو لرابع كلوريد الكربون (0.3 مجم / كجم من وزن الجسم) منفردين أو مجتمعين معا. وقد إشمئت هذه الإختبارات على قياس مستوى الدهون فوق المؤكسدة ومحتوى الجلوتاثيون و بعض المعايير الدموية بالإضافة إلى وظائف الكبد. وقد أظهرت النتائج ان التعرض لجرعات مجزأة من أشعة جاما أو المعالجة برابع كلوريد الكربون ينتج عنهما زيادة ملحوظة فى مستوى الدهون فوق المؤكسدة مصحوبا بنقص واضح فى محتوى الجلوتاثيون و عدد كرات الدم البيضاء و الحمراء و الصفائح الدموية ونسبة الهيموجلوبين فى الدم. كما لوحظت زيادة ذو دلالة إحصائية فى نشاط إنزيمات الكبد مقارنة بالمجموعة الضابطة.

أما بالنسبة للمجموعات التى تم معالجتها بمادة البروانثوسيانيدىن قبل وأثناء الحقن برابع كلوريد الكربون أو التعرض للإشعاع فقد أحدثت مادة البروانثوسيانيدىن تحسنا ملحوظا فى معظم المعايير المختبرة. وقد ألفت هذه الدراسة الضوء على الدور الوقائى لمادة البروانثوسيانيدىن فى مواجهة مثل هذه العوامل البيئية الخطرة خاصة ان مادة البروانثوسيانيدىن هى مستخلص نباتى طبيعى لم يعرف له أية آثار ضارة حتى الان.
