Abstract

Background: An adnexal mass (mass of the ovary, fallopian tube, or surrounding connective tissues) is a common gynecologic problem. Early diagnosis and intervention is essential especially in younger women to conserve the ovarian function. **Aim of the Work:** to evaluate the usefulness and value of Doppler and 3D Ultrasound as a method to enhance differentiation between benign and malignant pathologies before surgical intervention in women having adnexal swellings. **Patients and Methods:** This study was carried out in Obstetric and Gynecology Departments in Al-Azhar University Hospitals on 30 patients who had a preliminary diagnosis of an adnexal mass. After history taking and clinical examination, all patients underwent abdominal sonographically, Doppler examination and 3D ultrasound scan from April 2017 to September 2018. **Results:** Women with malignant masses were older than those with benign masses (46.00±9.76 vs 44.50±7.62 years) respectively. BMI in benign cases was lower than recorded in malignant cases (30.13±3.21 vs 38.57±0.81) with statistical significant difference between two them (P <0.01). Malignant cases were higher in postmenopausal 4(67 %) while Benign masses were higher in premenopausal 19 (79.2%) while, five cases (83%) of malignant cases were nulliparous. Regarding the diagnostic accuracy for the prediction of adnexal malignancy with 3DPD histogram analysis have been satisfied. Resistance index (RI) in benign cases ranged from 0.50-1.90 with mean value 1.18±0.41 and in malignant cases ranged from 0.30-1.50 with mean value 0.77±0.50. Sensitivity, specificity, PPV, NPV of RI was 78.8%, 75.0%, 77.2% and 76.1% respectively. Pulsatility index (PI) in benign cases ranged from 0.61-2.50 with mean value 1.80±0.52 and in malignant cases ranged from 0.80-1.37 with mean value 1.09±0.24. Sensitivity, specificity, PPV, NPV of PI was 90.9%, 88.0%, 91.0% and 86.5% respectively Peak systolic velocity (PSV) in benign cases ranged from 2.00-11.00 with mean value 6.88±2.71 and in malignant cases ranged from 14.00-35.00 with mean value 22.83±7.31. Sensitivity, specificity, PPV, NPV of PSV was 100%, 100%, 100% and 100% respectively. There was statistical significant difference between two studied groups regarding to resistance index, pulsatility index and peak systolic velocity (P < 0.05). The high risk was higher in malignant cases with 5 (83.3%) and lower in benign cases (1; 4.2%). There was statistical significant difference between two studied groups regarding to 3D ultrasound examination (P < 0.05). Conclusion: 3D ultrasound with color Doppler scan characteristics are found to be very important for discriminating benign from malignant tumors. **Key words:** Doppler, 3D ultrasound, benign/malignant pathologies, nature of adnexal swelling

Introduction

Adnexal swellings or masses represent a spectrum of conditions from gynecological and non-gynecologic sources. Gynecological sources include the ovaries, fallopian tubes, ectopic pregnancy, tuboovarian abscess, paratubal or paraovarian cyst, hydrosalpinx and broad ligament leiomyoma⁽¹⁾. Non-gynecologic sources of adnexal swellings include appendiceal abscess, appendicitis, bladder diverticulum, nerve sheath tumor, pelvic kidney, peritoneal cyst, and gastrointestinal carcinoma⁽²⁾.

Adnexal masses are considered a group of the most common diseases in gynecology, ovarian tumors, alone, represent two thirds of these cases. The American Cancer Society estimates that 22,280 new cases of ovarian cancer will be diagnosed in 2016 and 14,240 women will die from the disease.

Although ovarian cancer is the 17th most common cancer in women, it is the fifth most common cause of cancer death in woman, accounting for 5% of cancer deaths—more than any other gynecologic cancer⁽³⁾.

Non neoplastic conditions of the ovary that may present as adnexal masses include the following: pregnancy luteoma, hyperplasia of ovarian stroma, hyperthecosis, massive edema, solitary follicle cysts and corpus luteal cysts, multiple follicle cysts (polycystic ovaries), multiple luteinizing follicle cysts and/or corpora lutea, endometriosis, surface epithelial inclusion cysts (germinal inclusion cysts), simple cysts, inflammatory lesions, and paraovarian cysts⁽⁴⁾.

The differential diagnosis of adnexal masses remains a clinical challenge, but an accurate diagnosis is essential for adequate management.

Ultrasound is considered as the first-line diagnostic imaging tool for this task. In spite of the development of different scoring systems and logistical models, the examiner's subjective impression remains the best method of discriminating between benign and malignant adnexal masses⁽⁵⁾.

Doppler examination of a pelvic mass has to be performed when there are masses which are strongly suspected to be malignant. Clearly benign masses don't need such examination. Nevertheless Doppler examination may be very useful in the interpretation of a mass which isn't clearly benign⁽⁶⁾.

Three-dimensional (3D) ultrasound is a new imaging technique that has become currently available in gynecologic practice, specifically in gynecologic oncology⁽⁷⁾. 3D ultrasound is an easy and noninvasive method for the differential diagnosis of various physiological and pathological conditions of the adnexal masses in the clinical practice of obstetrics and gynecology. The 3D improves spatial orientation and access multiplanar views, especially the coronal (reconstructed) plane, which can provide additional information that can depict lesions not easily diagnosed by two-dimensional (2D) ultrasound imaging⁽⁸⁾.

In addition, 3D power-Doppler ultra-sonography allows a 3D reconstruction of the vascular network and also calculating vascular indices based on the total and relative amount of power Doppler information within the volume of interest⁽⁹⁾.

Aim of the Work

The aim of the work was to study the usefulness and value of Doppler and 3D Ultrasound as a method to enhance differentiation between benign and malignant pathologies before surgical intervention in women having adnexal swellings.

Patients and Methods

A) Patients

This prospective study carried in Obstetric and Gynecology Departments in Al-Azhar University Hospitals. 30 patients who had a preliminary diagnosis of an adnexal mass, which was detected clinically and confirmed sonographically to be adnexal masses were included regardless the patients' complaint, age or parity, and scheduled for surgical intervention from April 2017 to September 2018.

The study was approved by the Ethical Review Board of Al-Azhar University Hospitals and all women gave written informed consent.

Inclusion criteria

- Patients aged between 18 and 80 years old.
- Approval of a transvaginal ultrasound scan and informed consent provided.

Exclusion criteria

- Women who pregnant at the time of diagnosis,

- Women underwent surgery at a different center
- If their management was according to expectant follow-up

B- Methods

All patients subjected for the following:

I Full history taking:

- Detailed personal, present, past, family, obstetric, menstrual and contraceptive history including risk factors for ovarian cancer include age older than 60 years; early menarche; late menopause; nulliparity; infertility; personal history of breast or colon cancer; and family history of breast, colon, or ovarian cancer.
- History of risk factors for ectopic pregnancy (medical history of tubal ligation or other tubal surgery, pelvic inflammatory diseases, or use of an intrauterine device).

II General Examination:

- Vital signs, height and body build and other system examination.
- Cervical, supraclavicular, axillary, and inguinal lymph nodes examination.
- Measurements of body weight and height and subsequently calculation of their BMI (weight in Kg/height² in meter)

III Abdominal Examination

- Inspection, palpation, percussion and auscultation.
- A detailed abdominal examination to assess for ascites, masses, tenderness and hepatosplenomegaly.

IV Pelvic Examination

- PV examination, bimanual and speculum examination to assess the size, tenderness, location, consistency, and mobility of the uterus and both adnexa.
- A rectovaginal examination was done to assess reveal tenderness or nodularity of the uterosacral ligaments.

V Routine Investigations

- Liver function tests and serum creatinine.
- Complete blood count (CBC).
- Prothrombin time (PT)

VI Radiological Investigations

- Abdominal ultrasound examination was performed in patients with a large or suspicious mass to assess the intra-abdominal spread.
- Doppler examination.
- 3D ultrasound scan performed by staff gynecologists or one expert gynecologist with a special interest in gynecological ultrasound.

Ultrasound assessment included following strategy

- Initially, all masses were evaluated by gray-scale ultrasound according to the pattern-recognition approach and using the International Ovarian Tumor Analysis (IOTA) terms and definitions. Masses

observed with a typical appearance of a benign cyst, such as endometrioma, mature teratoma, simple/serous cyst, hydrosalpinx, paraovarian cyst, hemorrhagic cyst, mucinous cyst or peritoneal cyst were considered as being at low risk for malignancy and did not undergo further assessment by ultrasound.

- Masses with ascites and/or sonographic signs of carcinomatosis were considered as being at high risk for malignancy and did not undergo further assessment except for transabdominal ultrasound to assess the intra-abdominal spread.
- Masses that did not show ascites and/or signs of intra-abdominal carcinomatosis and could not be classified as certainly benign according to pattern recognition and showed solid components (thick papillary projections, irregular internal wall or solid areas), as well as solid tumors, were considered as being at intermediate risk for malignancy. These intermediate-risk masses underwent second-step analysis and were evaluated by two-dimensional (2D) PDA to determine the location and quantity of color signals (IOTA color score) within the mass and specifically within the solid components. When the mass was considered as high risk

following 2D-PDA, the patient underwent third-step assessment by subsequent 3D-PDA.

VII - Histopathological Examination of the specimen after operation: All samples will be examined by Histopathologist. Histological confirmation of the finding will be done in all patients

Statistical Analysis:

Analysis of data was done by IBM computer using SPSS Inc., (Statistical Program for Social Science Inc.,) Chicago, IL, USA, version 20.00 as follows:

Qualitative data were expressed as frequency and percentage. Chi-square test (Fisher’s exact test) was used to examine the relation between qualitative variables. Numerical data were expressed and presented in terms of range, mean, standard deviation and percentages. For quantitative data, comparison between two groups was done using “Mann-Whitney test”. Student test was used to determine significance between 2 tail variables. Level of significance (probability "P" value) is evaluated, where P value <0.05 is of significant.

Results

Table (1): Final diagnosis of 30 adnexal masses According to IOTA simple rules

Histology	N	%
Benign tumor (n=24)	24	80
Endometriotic cyst	7	23.3
Dermoid cyst	4	13.3
Fibroma	4	13.3
Mucinous adenoma	4	13.3
Haemorrhagic cyst	3	10.0
Serous adenoma	1	3.3
Ovarian abscess sequelae	1	3.3
Malignant tumor (n=6)	6	20
Serous borderline tumor	2	6.7
Serous carcinoma	2	6.7
Endometrioid carcinoma	1	3.3
Metastatic tumor	1	3.3
Total	30	100

Demographicsdata of patients:

Table (1) shows comparison between benign and malignant cases regarding demographic data. Age in benign cases ranged from 34-60 with mean value 44.50±7.62 and in malignant cases ranged from 35-57 with mean value 46.00±9.76. BMI in benign cases ranged from 26.50-36.50 with

mean value 30.13±3.21 and in malignant cases ranged from 37.70-39.80 with mean value 38.57±0.81. There was statistical significant difference between two studied groups regarding BMI (P < 0.05) while there was no statistical significant difference regarding age (P>0.05).

Table (2): Comparison between benign and malignant cases regarding demographic data

Item	Benign cases “n=24”	Malignant cases “n=6”	p-value
Age			
Range	34.00-60.00	35.00-57.00	0.686
Mean±S.D.	44.50±7.62	46.00±9.76	
BMI			
Range	26.50-36.50	37.70-39.80	0.001*
Mean±S.D.	30.13±3.21	38.57±0.81	

Table (2): shows maternal history of benign and malignant cases. Regarding to menopausal status, benign masses were higher in premenopausal 19

(79.2%) while malignant cases were higher in postmenopausal 4(67 %). Five cases (83%) of malignant cases were nulliparous. There was no

statistical significant difference between two studied groups regarding maternal history and parity (P > 0.05).

Table (3): Maternal history of benign and malignant cases

	Benign cases "n=24"		Malignant cases "n=6"		P value
	No	%	No.	%	
Menopausal status					
Premenopausal	19	79.2	2	33.0	0.175
Postmenopausal	5	20.8	4	67.0	
Parity					
Nulliparous	4	16.7	5	83.0	0.388
Parous	20	83.3	1	17.0	

Table (4) shows family history in the two studied groups. Family history cases in benign group were 14(58.3%) and in malignant group were 3(33.3%) while family without history was

10(41.7%) and 4(66.7%) respectively. There was no statistical significant difference between two studied groups regarding family history (P > 0.05).

Table (4): Family history in the two studied groups

Family history	Benign cases "n=24"		Malignant cases "n=6"		P value
	No	%	No.	%	
No	10	41.7	4	66.7	0.261
Yes	14	58.3	2	33.3	

Table (5) shows contraceptive history in relation to histopathological Examination. Contraceptive history cases in benign group were 10(41.7%) and in malignant group were 2(33.3%) while cases without contraceptive history were

14(58.3%) and 4(66.7%) respectively. There was no statistical significant difference between two studied groups regarding contraceptive history (P > 0.05).

Table (5): Contraceptive history in relation to histopathological Examination

Contraceptive history	Benign cases "n=24"		Malignant cases "n=6"		P value
	No	%	No.	%	
No	14	58.3	4	66.7	0.545
Yes	10	41.7	2	33.3	

Table (6) shows obstetric, menstrual in relation to Histopathological Examination. Obstetric and menstrual cases in benign group were 13(54.2%) and in malignant group were 3(50%) while cases

without obstetric, menstrual were 11(45.8%) and 3(50%) respectively. There was no statistical significant difference between two studied groups regarding obstetric, menstrual (P > 0.05).

Table (6): menstrual history regularity in relation toHistopathological Examination

menstrual history regularity	Benign cases "n=24"		Malignant cases "n=6"		P value
	No	%	No.	%	
No	11	45.8	3	50.0	0.605
Yes	13	54.2	3	50.0	

Table (7) shows pelvic inflammatory diseases in relation to histopathological examination. Pelvic inflammatory diseases cases in benign group were 12(50%) and in malignant group were 4(66.7%) while cases without Pelvic inflammatory diseases were

12(50%) and 2(33.3%) respectively. There was no statistical significant difference between two studied groups regarding pelvic inflammatory diseases (P > 0.05).

Table (7): Pelvic inflammatory diseases in relation tohistopathological examination

Discussion

An adnexal mass (mass of the ovary, fallopian tube, or surrounding connective tissues) is a common gynecologic problem. Early diagnosis and intervention is essential especially in younger women to conserve the ovarian function⁽¹⁰⁾.

Good preoperative discrimination between benign and malignant adnexal mass results in more women with malignancy being correctly referred for gynaecologic oncology care and more women with benign masses undergoing conservative management⁽¹¹⁾.

Ultrasonography is one of the most evaluated methods for early detection of ovarian cancer. In clinical practice, detected adnexal masses can be classified according to International Tumor ovarian Analysis (IOTA) "simple rules". IOTA simple rules are based on the identification of some simple features during conventional ultrasound examination and presents high sensitivity⁽¹²⁾. However, the false positive rate is elevated. About 40-50% of the women with inconclusive and malignant results by IOTA simple rules have benign ovarian tumors⁽¹³⁾.

Three-dimensional ultrasonography allows quantifying blood flow and vascularization in ovarian tumors. Resistance index, pulsatility index and peak systolic velocity can be calculated after manual outlining of vascularized solid areas within the tumor or after spherical sampling from the most vascularized area of the tumor, the area is selected by the examiner and the spherical sampling performed automatically by the software⁽¹⁴⁾.

In this study, our objective was to evaluate the usefulness and value of Doppler and 3D Ultrasound as a method to enhance differentiation between benign and malignant pathologies before surgical intervention in women having adnexal swellings.

This study was carried in obstetric and Gynecology Departments in Al-Azhar University Hospitals on 30 patients who had a preliminary diagnosis of an adnexal mass, which was detected clinically and confirmed sonographically to be adnexal masses.

By histopathological examination of adnexal masses, there appeared to be 24 (80%) benign adnexal masses and 6 (20%) malignant adnexal masses. Among 24 benign adnexal masses, there were 7 endometriotic cyst, 4 dermoid cyst, 4 fibroma, 4 mucinous adenoma, 3 haemorrhagic cyst, one serous adenoma and one ovarian abscess sequelae. While among the 6 malignant masses, there were two serous borderline tumors, two serous carcinoma, one endometrioid carcinoma, and one metastatic tumor.

The prevalence of malignant cases in our sample was similar to **Geomini *et al.***⁽¹⁵⁾ where there were 80% benign adnexal masses and 20% malignant adnexal masses. Among the 26 malignant masses, there were 16 serous adenocarcinomas, two mucinous adenocarcinomas, two endometrioid carcinomas, three clear cell carcinomas, two undifferentiated adenocarcinomas of the ovary, and one coeloma carcinoma.

Prevalence of malignancy in our sample was relatively lower than **Czekierdowski *et al.***⁽¹⁶⁾ that revealed 25.3% of tumors were proved to be malignant, and 74.7% were proved to be benign. **Dotlic *et al.***⁽¹⁷⁾ showed that there were significantly more benign (63%) than malignant (37%) tumors.

As regard to age of participating women, women with benign cases was younger than those with malignant cases representing 44.50 ± 7.62 vs 46.00 ± 9.76 years respectively which is similar to several studies done by **Radhamani and Akhila**⁽¹⁸⁾ they reported that, patients with malignant HP findings were significantly older than those with benign adnexal masses.

BMI in benign cases ranged from 26.50-36.50 with mean value 30.13 ± 3.21 lower than

recorded in malignant cases (37.70-39.80 with mean value 38.57 ± 0.81) with statistical significant difference between two studied groups ($P < 0.01$). Similar to our findings, **Dotlic *et al.***⁽¹⁷⁾ concluded that BMI values were highly significantly higher in the patients with malignant adnexal tumors ($p = 0.001$). Also **Terzic *et al.***⁽¹⁹⁾ revealed significant differences among tumor types regarding the women's BMI ($P=0.000$). Women who had benign tumors had the lowest BMI. The majority of women with malignant tumors were overweight (BMI: 25-29.99), while most women with benign tumors had normal weight (BMI: 18-24.99) ($P=0.000$).

The results of our study correspond with the literature data, that there is a statistically highly significant correlation between higher values of BMI and malignant HP findings of adnexal masses⁽²⁰⁾.

Regarding to menopausal status, 21 (70%) women were premenopausal and 9 (30%) were postmenopausal. Benign masses were higher in premenopausal 19 (79.2%) while malignant cases were higher in postmenopausal 4 (67%). Five cases (83%) of malignant cases were nulliparous. There was no statistical significant difference between two studied groups regarding maternal history and parity ($P > 0.05$). **Radhamani and Akhila**⁽¹⁸⁾ study has similar results, but was not statistically different, whereas other studies have reported more association with malignant disease. **Alcázar *et al.***⁽²¹⁾ found that 67% of women were premenopausal, and 33% were postmenopausal, while **Utrilia-Layna *et al.***⁽⁵⁾ found that 64.6% were premenopausal and 35.4% were postmenopausal. **Dotlic *et al.***⁽¹⁷⁾ and **Terzic *et al.***⁽¹⁹⁾ revealed that malignant were more frequent in postmenopausal women ($P < 0.05$).

The higher percentage of malignant ovarian tumors in postmenopausal women in the present study confirms the characteristic of malignant ovarian tumors being more common in postmenopausal women. on the other hand, patients in the reproductive period more often have benign lesions.

Contrary to what might be expected, in the examined population, the number of pregnancies did not show a significantly different distribution between benign and malignant adnexal masses. Therefore, pregnancy cannot be considered a clear predictive factor that could help in preoperative evaluation of adnexal masses⁽¹⁷⁾.

From a clinical point of view of studied cases: most patients presented with lower abdominal pain (12; 40%), abdominal distention (5; 17%), multiple symptoms (5; 17%), asymptomatic (4; 13%) and menstrual disorders (4; 13%). In agree with our results, women in **Terzic *et al.***⁽¹⁹⁾ study were either

asymptomatic or suffered from pain, abdominal swelling, bleeding, urinary disturbances, etc. There were no significant differences among tumor types regarding the symptoms that examined women suffered from ($P=0.082$). In **Utrilla-Layna *et al.***⁽⁵⁾ study, most patients (50.7%) were asymptomatic, 27.8% complained of abdominal symptoms (abdominal discomfort, swelling, bloating, constipation, diarrhea or increase in abdominal size), 5.4% complained of pelvic or lower back abdominal pain and 1.1% complained of menstrual disorders.

As regard to laboratory findings, there was statistical significant difference between two studied groups regarding WBC ($P < 0.05$) while, there was no statistical significant difference regarding RBCs, Hb, HTC and prothrombin time ($P > 0.05$). Although contrary to usual findings⁽²²⁾ and our expectations, no other investigated parameter (blood analyses, sedimentation, biochemical analyses) in our population had a statistical significance as a risk factor that could imply to the malignant nature of the tumor, so, in a preoperative tumor evaluation and in the process of deciding on the radicalism of the procedure, they cannot be considered reliable.

Results regarding the diagnostic accuracy for the prediction of adnexal malignancy with 3DPD histogram analysis have been satisfied. Resistance index (RI) in benign cases ranged from 0.50-1.90 with mean value 1.18 ± 0.41 and in malignant cases ranged from 0.30-1.50 with mean value 0.77 ± 0.50 . Sensitivity, specificity, PPV, NPV of RI was 78.8%, 75.0%, 77.2% and 76.1% respectively

Pulsatility index (PI) in benign cases ranged from 0.61-2.50 with mean value 1.80 ± 0.52 and in malignant cases ranged from 0.80-1.37 with mean value 1.09 ± 0.24 . Sensitivity, specificity, PPV, NPV of PI was 90.9%, 88.0%, 91.0% and 86.5% respectively

Peak systolic velocity (PSV) in benign cases ranged from 2.00-11.00 with mean value 6.88 ± 2.71 and in malignant cases ranged from 14.00-35.00 with mean value 22.83 ± 7.31 . Sensitivity, specificity, PPV, NPV of PSV was 100%, 100%, 100% and 100% respectively.

There was statistical significant difference between two studied groups regarding to resistance index, pulsatility index and peak systolic velocity ($P < 0.05$).

Czekierdowski *et al.*⁽¹⁶⁾ revealed statistically significant differences between benign and malignant tumors were found for PI (1.06 vs 0.76; $p = 0.001$), RI (0.62 vs 0.51; $p = 0.002$), VI (0.55 vs 1.52; $p = 0.002$), VFI (0.18 vs 0.49; $p = 0.001$). However, the highest sensitivity of 3D indices for malignant tumor detection was found for FI (42.9%). Specificity of 2D and 3D indices was

between 93.6% for VI to 98.2% for RI. Accuracy and positive and negative predictive values were found to be between 66.8% to 79.8% respectively. AUROC's analysis indicated that the most useful test for the discrimination between benign and malignant tumors was VI followed by VFI and PI with RI.

In the previous studies, some authors suggested the existence of clear cut-off values for RI and PI of benign and malignant tumours; **Timor Tritsch *et al.***⁽²³⁾ reported the RI value of 0.4 had sensitivity 93.8% and specificity of 98.7%. **Alcázar and Jurado**⁽⁷⁾ preferred 0.45. **Laban *et al.***⁽²⁴⁾ also reported that the best RI cut-off value was < 0.48 giving a sensitivity, specificity, and accuracy of 90%, 89%, and 90%. **Medeiros *et al.***⁽²⁵⁾ in their systematic review showed that Doppler can detect malignant masses when the RI was < 0.50 . **Ueland *et al.***⁽²⁶⁾ reported sensitivity and specificity of 52.8% and 77.6% respectively using cut-off value of $PI < 1$. In spite that we found that low $PI < 1$ was an important feature of malignancy (80.4 %) but $PI < 1$ was also found in 15.7% of benign masses. So PI alone cannot be a reliable feature to detect malignancy.

In **Alcázar *et al.***⁽²⁷⁾, 99 non-consecutive women diagnosed as having an adnexal mass were assessed by transvaginal power Doppler ultrasound. 41 masses were malignant and 58 were benign. Agreement between real-time ultrasound and 3D volume analysis was good for both off-line examiners. Sensitivities for real-time ultrasound and 3D volume analyses were 100%, 93% and 90%, respectively ($p > 0.05$). Specificities for real-time ultrasound and 3D volume analyses were 91%, 84% and 86%, respectively ($p > 0.05$).

Fagotti *et al.*⁽²⁸⁾ evaluated 51 premenopausal women with unilocular-solid adnexal cysts to determine the diagnostic performance of different ultrasound parameters for discriminating benign from malignant lesions. They found that color Doppler, provided a 100% sensitivity and 80% specificity for distinguishing benign and BOT lesions from invasive carcinoma.

Abbas *et al.*⁽²⁹⁾ As regards to Doppler indices in the present study, RI and PI values were calculated for each mass. The mean value of RI was 0.79 for benign masses and 0.50 for malignant masses, while the mean value of PI was 1.66 for benign masses and 0.82 for malignant masses. These values, in correlation to various studies using "0.42" and "1" values for RI and PI respectively as a cutoff value for prediction of malignancy reflected that, RI had a sensitivity of 44% and a specificity of 99%, while PI had a sensitivity of 80% and a specificity of 84%. P-value was < 0.001 for both RI and PI among both groups being of significant value in predicting malignancy of adnexal masses.

Radhamani and Akhila ⁽¹⁸⁾ concluded that, sonography (transvaginal and transabdominal) is a sensitive method for detecting ovarian cancer. Their study showed that abdominal sonography had a sensitivity of 87.5% and a specificity of 95.65% with an accuracy of 95% for predicting ovarian cancer which is similar to a study by **Pourissa *et al.*** ⁽³⁰⁾.

In some studies, the sensitivity of power Doppler diagnostics for prediction of malignancy was up to 75% ⁽¹⁹⁾. However, **Ohel *et al.*** ⁽³¹⁾ reported that no significant differences were noted between benign and malignant ovarian tumors for all three indices of vascularity and perfusion on 3DPD ultrasound.

In current study, high risk was higher in malignant cases with 5 (83.3%) and lower in benign cases it is (1; 4.2%). There was statistical significant difference between two studied groups regarding to 3D ultrasound examination ($P < 0.05$).

In agree with our results, **Utrilia-Layna *et al.*** ⁽⁵⁾ studied 223 women, 60.8% masses were considered as being at low risk for malignancy, 8.2% as being at high risk for malignancy and 31.1% as being at intermediate risk for malignancy. Among the 223 considered as low risk, final histology was benign in 221 cases and malignant in two cases. On definitive histological analysis, all 30 cases considered as high risk were malignant and among the 114 cases considered as intermediate risk, 60 were benign tumors and 54 were malignant lesions.

Our results also were in agree with previous a previous study by **Huchon *et al.*** ⁽³²⁾. They found that cases with a very high risk of malignancy have higher risk scores of 3D-PDA.

Conclusion:

- 3D ultrasound with color Doppler scan characteristics are found to be very important for discriminating benign from malignant tumors.
- 3D PD imaging has diagnostic potential for the discrimination of benign and malignant complex adnexal masses, but specific, possibly most vascularised areas of each tumor have to be examined in detail to improve this method.
- Ultrasonography has the possible advantage of earlier detection and, therefore, improved survival and avoidance of unnecessary surgery.
- The risk of malignancy is decreased among younger and premenopausal women, who had a prolonged breast-feeding. Symptoms that are associated with ovarian cancer are typically nonspecific. High BMI can be a risk factor for malignancy.
