Abstract:
Sitagliptin is highly selective dipeptidyl peptidase-4 (DPP-4) inhibitor that is considered as one of the new oral therapies for management of type II diabetes. Because of the sitagliptin unknown effects on the endocrine part of the pancreas, especially on the cellular levels, this study was done to evaluate its effect on the endocrine part of the pancreas in experimentally-induced type II diabetic in adult albino rats.

Material and Methods: The present study was carried out on 30 adult male albino rats which were divided into; Group I (untreated control group), Group II (diabetic group), where type II diabetes had been induced via alloxan intake and group III (treated group), where 0.14 mg/100 mg B.W. sitagliptin was given orally per day for 3 weeks after induction of type-2 diabetes. The specimens were prepared for light microscopic examination. In parallel, the related biomedical parameters such as serum glucose and serum insulin levels had been estimated, statistically analyzed and compared between the three groups.

Results: Sections of pancreas taken from diabetic rats showed morphological changes in islets of Langerhans cells in the form of pyknotic nuclei, cytoplasmic vacuolation, poor differentiation and abnormal shape and size of the cells. These morphological changes had been partially recovered in diabetic rats treated with sitagliptin. Also, the hyperglycemia and hypoinsulinemia that was detected in the control diabetic group had been nearly returned to normal after sitagliptin treatment.

Conclusion: Sitagliptin drug has improved islet functions on both morphological and biomedical parameters in type II diabetic rats and can be taken into consideration as one of the new oral anti-diabetic drugs on the human level that need to be more investigated.

Keywords: Sitagliptin, Type II Diabetes, Dipeptidyl Peptidase-4 (DPP-4) inhibitors Albino rats, Alloxan.

Introduction:
Currently, there are various pharmaceutical drugs for the management of type 2 diabetes. According to the UKPDS study, most of the available oral therapies for diabetes fail with time. This failure is probably due to the progressive decline in beta cell function (UKPDS, 1998). On the other hand, most of these medications that are commonly used such as thiazolidinediones (TZDs), sulfonylureas, and insulin are associated with significant weight gain (UKPDS 1998). New therapies such as incretins may have an effective role in reducing hemoglobin A1c (HbA1c) through keeping beta cell functioning and without causing weight gain. Two groups are included in this class;
incretin mimetics (Glucagon-like peptide (GLP-1) analogues such as Exenatide) and incretin enhancers (Dipeptidyl-peptidase four (DPP4) inhibitors, such as Sitagliptin) (Halimi, 2008).

Dipeptidyl Peptidase-4 (DPP-4) inhibitors work through inhibition of the DPP-4 enzyme that is responsible of degrading incretin hormones such as glucagon like peptide (GLP)-1 and glucose-dependent insulinotropic polypeptide (GIP) (Mest and Mentlein 2005). Inhibition of DPP-4 enzyme stabilizes the intact or active form of the incretin hormones (Ahren andSchmitz 2004). Active GLP-1 and GIP stimulate glucose dependent insulin biosynthesis and release. Moreover, GLP-1 suppresses release of glucagon, delays stomach emptying, and increases satiety (Holst and Gromada 2004). In rodent, DPP-4 inhibitors improved insulin secretion, glycemic control, and beta cell function (Ahren et al., 2000; Pospisil et al., 2002; Reimer et al., 2002). In type 2 diabetic patients, treatment with DPP-4 inhibitors decreased postprandial glucose excursion, fasting plasma glucose (FPG), and HbA1c. Moreover, in relation to placebo, DPP-4 inhibitors have been shown to be well tolerated with neutral weight effects with low incidence of hypoglycemia and gastrointestinal adverse events (Ahren et al., 2002; Ahren et al., 2004a; Ahren et al., 2004b).

Sitagliptin is highly selective DPP-4 inhibitor that can be used through oral route. In sitagliptin-treated rodents, plasma DPP-4 activity was inhibited (up to 80%) and the active GLP-1 levels were elevated (up to 3 folds). Moreover, after an oral glucose tolerance test, glucose excursion showed nearly a maximal reduction (Kimet et al., 2005).

Furthermore, when single doses of sitagliptin (up to 600 mg) were given to healthy men, it was well tolerated and no hypoglycemia, weight gain or gastrointestinal problems had been detected (Herman et al., 2005; Brain et al., 2006). In addition, sitagliptin inhibits plasma DPP-4 enzyme activity and augments active GLP-1 levels in a dose dependent manner and its pharmacokinetic (PK) profile is consistent with once-daily dose (Herman et al., 2005). Moreover, sitagliptin has been found to be effective and safe as an add-on therapy to insulin in reducing blood glucose levels in patients whose lack the ability of endogenous insulin secretion (Eiji., 2011).

From the above mentioned data, it seems that there is cumulative data that support the role of sitagliptin as one of considerable oral anti-diabetic drugs for management of type 2 diabetes. However, lacking of the studies, especially the histological studies on the cellular and molecular levels, considering sitagliptin effect on the endocrine part of the pancreas weaken this consideration. This work aimed to study the histological and biochemical changes that may occur in the endocrine part of the pancreas of alloxan-induced type II diabetic adult albino rats after treatment with sitagliptin.
Material & Methods:

This study was carried out on 30 adult male albino rats ranging in weight from 150 - 200 grams each. All animals were kept in clean ventilated cages under similar environmental conditions and were fed the same laboratory diet.

They were divided randomly into three equal groups; the first group "Group I" was considered as a Control group and did not undergo any intervention, while the second and third groups were subjected to induction of type II diabetes via single injection of alloxan (120 mg/kg) intraperitoneally (Malaisse, 1982). The second group "Group II" was considered as a Diabetic Group where induction of diabetes was not followed by any further medical intervention, while the third group "Group III" was considered as a "Treated Group" where induction of diabetes was followed by treatment with sitagliptin (0.14/100 mg B.W.) orally for 21 days. The dose was calculated according to Paget and Barnes (1964).

Parameters of the study:
A) Microscopic study: Fresh sections from the pancreas of the three groups were prepared for paraffin sections, 6 mm thickness, and stained by hematoxylin (Hx) and eosin (E) stains (Clayden, 1971) and modified aldehyde fuchsin (Halami 1952). After that, the stained sections were examined via light microscope, photographed and all the detected variations between the three groups on the level of the microscopic findings had been scientifically discussed.

B) Biomedical and laboratory findings: Collection of rats' blood serum was taken to estimate the following parameters:
1) Serum glucose level: Using enzymatic colorimetric method (Trinder, 1984).
2) Serum insulin level: According to the method used by (Reeves, 1983).

C) Statistical analysis: the obtained results were statistically evaluated and analyzed using SPSS-14 system.

Results:

I-Microscopic examination:-
A- Control group (GI):-

Examination of Hx&E stained sections of pancreas from the control group, revealed normal appearance of the islets of Langerhans, they irregularly scattered within the exocrine pancreatic acini. The islet appeared as pale spheroid masses with rich vascular supply.

Each islet is formed of numerous cells with central spherical nuclei. Beta cells are the most abundant cells and occupy the core of the islets and contain numerous granules. Alpha and delta cells are observed at the periphery of the islets (Figs. 1, 2).

Sections stained with modified aldehyde fuchsin showed B-cells which were distributed all over the islet, while other cells were stained yellow and tend to be at the periphery of the islets (Figs. 3, 4).

B-Diabetic group (GII):-

Examination of Hx&E stained sections, showed that the islets were irregular in outline and showed marked reduction in
its size. The islet cells were poorly differentiated. Decreased islet cellularity was observed (Figs.5,6). Some islet cells showed marked degenerative changes and have very small pyknotic nuclei (Fig. 7). Also, marked vascular degenerative changes had been detected at the region of islet suggesting arteritis (Fig.8).

Section stained with modified aldehyde fuchsin showed that most of islet cells were affected. The cells showed cytoplasmic vacuolation, pyknosis and karyolysis of their nuclei (Figs.9,10).

**C- Sitagliptin treated group (GIII):**

Examination of Hx&E stained sections of the diabetic group which was treated by sitagliptin showed partial return to the normal cellular distribution in the islet of Langerhans and increased cellularity with ill differentiation of the different cell types (Figs.11&12).

In modified aldehyde fuchsin stain sections of this group showed mild increase in the number of Beta cells and the islets appeared more organized with less vacuolated cells, but the cells were still poorly differentiated (Figs.13,14).

**II-Biochemical parameters:-**

Changes in the serum level of blood glucose and insulin are demonstrated in the following table and histograms which showed partial recovery of both levels to their values in the control group (Table 1 &Histogram.1, 2, 3). A $P<0.05$ was taken indicate statistical significance. Results are reported as average±SE.

Discussion:
Type II Diabetes is characterized by progressive deterioration in functions of the beta cells as it is usually associated with 50% loss of the beta cells mass and 60% necropsy at the time of diagnosis (Lebovitz, 2002). This decline in the beta cell mass is suggested to be due to accelerated apoptosis and is motivated by glucotoxicity, lipotoxicity, proinflammatory cytokines, leptin and islet cells amyloid (Wajchenberg, 2007). Using drugs such as incretin mimetics or enhancers has demonstrated antiapoptotic effect with clinical evidence of their beneficial effect on the human beta cell function (Wajchenberg, 2007).

Incretin hormones are released from the digestive tract in response to food intake and these hormones enhance glucose dependant insulin secretion from the pancreas, maintain glucose homeostasis through slowing of gastric emptying, inhibit glucagon secretion and increase satiety. Of the two major incretins, glucagon-like peptide (GLP-1) and glucose-dependant insulinotropic polypeptide (GIP), only GLP-1 or its or enhancers (mimetics) have an effect on beta cell function (Drucker, 2006).

Several GLP 1 analogues known as “incretin mimetics” have been developed and are available as injectable forms (e.g. Exenatide and Liraglutide) or oral forms (e.g. Sitagliptin and Vildaglipin). Sitagliptin exerts its effect through the inhibition of an active enzyme dipeptidyl peptidase 4 (DPP-4), thus it prevent the rapid inactivation of GLP1 active forms (Chia and Egan 2008). They added that, similar to GLP-1, DPP4 inhibitors increase glucose insulin mediated secretion and suppress glucagon secretion (Chia and Egan 2008). This study examined the influence of sitagliptin "DPP-4 inhibitor" over 3 weeks period on glucose tolerance, insulin secretion and islet morphology in normal and type II diabetic rats.
To do this study, induction of type II diabetes has been done via using alloxan. Alloxan was used to induce diabetes for two reasons; firstly, alloxan has a selective cytotoxic effect on beta cells (Okamoto 1984; Dunn et al., 1943). Secondly, alloxan injection leads to partial destruction of beta cells of the islets of Langerhans as it is rapidly uptaken by beta cells and has a direct effect on its cell permeability (Shafrir, 2003). For these reasons, alloxan is the drug of choice to experimentally induce type II diabetes in animal models.

In this study, islets of Langerhans in group II "control diabetic group" showed marked reduction of the islets size, poor differentiation of its cells, and decreased islets' cellularity. In parallel, these cellular changes were associated with marked degenerative changes in the vessels in the islets region suggesting arteritis. These results are supported with the previous studies that refer to glucotoxicity, lipotoxicity, and proinflammatory cytokines as possible motivators for exaggerated cellular apoptosis and inflammatory changes of the islets of Langerhans (Wajchenberg, 2007).

In this study, beta cells showed marked degenerative changes such as nuclear pyknosis, karyolysis, and cytoplasmic vacuolation. These degenerative changes were associated with marked hyperglycemia and hypoinsulinemia. According to Bolaffi et al (1986) and Kessler et al (1999), these degenerative changes are usually associated with abnormalities in islets functions with subsequent hyperglycemia and hypoinsulinemia. Moreover, beta cell mass in the diabetic group II had been shown to be reduced in size with poor differentiation of its cells in comparison to group I "control group". These size reduction and poor differentiation may be attributable to the induced beta cells apoptosis. This beta cell apoptosis had been also noticed at autopsy and in isolated islets from diabetes type II patients (Huang et al., 2007; Laybutt et al., 2007).

When diabetic rats were treated by sitagliptin in "Group III", partial recovery of the islets of Langerhans to the normal cellular distribution and increased cellularity of islets with mild increase in beta cells number has been detected. These changes were associated with mild improving in both blood glucose and insulin profiles. Mu et al (2009) and Verspohl (2009) in their studies reported similar findings in reducing glucose level, reducing HBA1c level and improving insulin reduction. Sitagliptin is probably doing its effects via increasing GLP-1 concentration. GLP-1 had been shown to reverse loss of beta cell mass in human and animal models of diabetes via increasing new beta cell formation and decreasing β-cell apoptosis (Buteau et al., 2001; Deacon & Holst 2002; Hui et al., 2003; Xu et al., 2006; Aschner et al., 2006; Raz et al., 2006; Poitout and Robertson 2008). These sitagliptin benefits on beta cell mass and function may have been mediated by either its direct effects on beta cells or indirect by its action to lower blood.
glucose. Hyperglycemia can contribute to both reducing beta cell mass, increasing beta cell apoptosis and loss of beta cell function. Poor differentiation of beta cells that was detected in this study results after sitagliptin treatment may be due to the short term treatment (21 days) may not give enough time for beta cells to be fully differentiated. In summary, sitagliptin had synergistic effects on preserving B-cell mass in the rat model of type II diabetes and is able to improve glucose intolerance via increasing beta cells replication and improving islet functions.

Effect of Sitagliptin on Pancreas of Adult White Rats in Cases of Experimental Diabetes (Microscopic and Biochemistry Study)

Tamer M. El-Sayed Abdou Gamal and Zinab M. Mahmoud Gable

In the Department of Histology - Faculty of Medicine (Boys - Girls) - Faculty of Medicine (Boys - Girls) - Al-Azhar University

Introduction and Objective of the Study:
Disturbances of diabetes span a large number of patients throughout the world, and this study aimed to investigate the effects of the sitagliptin drug on the pancreas of adult white rats in cases of experimental diabetes. A group of 30 rats from both sexes, of equal weight, were distributed into three equal groups. The first group served as a control group, which received a clear solution of the irritant, while the second group received sitagliptin orally in doses of 0.1 mg per 100 grams of the rat's weight for 12 days from the date of the disease. The third group received sitagliptin in the same way in experimental diabetes, in doses of 0.1 mg per 100 grams of the rat's weight. The study assessed the results to varying degrees in a microscopic study of the pancrease tissue for the changes that may occur in the different groups after using the hematoxylin and eosin stain and the periodic acid Schiff modified.

Results:
A significant increase in the number of beta cells in the islets of Langerhans, changes in the nuclei of the islets, and a decrease in blood glucose were observed. It was also noted that the blood sugar levels were reduced and the insulin levels in the blood increased after using the drug. Sitagliptin had a clear improvement in these changes and returned to the normal levels. It was concluded from this study that the sitagliptin drug has a significant role in improving the complications resulting from the effect of diabetes on the pancreas.
